

## Why

We use a normal random function model to make a regressor.

## Definition

Let  $F: \Omega \to (A \to \mathbf{R})$  be a normal random function with mean function  $m: A \to \mathbf{R}$  and covariance function  $k: A \times A \to \mathbf{R}$  over the probability space  $(\Omega, \mathcal{A}, \mathbf{P})$ . Let the family of random variables (or stochastic process) of F be  $f: A \to (\Omega \to \mathbf{R})$ .

Let e be a normal random vector with mean zero and covariance  $\Sigma_e$ . Let  $a^1, \ldots, a^n \in A$ . We sometimes call the sequence  $a^1, \ldots, a^n$  the design. Define  $y: \Omega \to \mathbb{R}^d$  by

$$y_i = f(a^i) + e_i$$

We call y the observation vector or observation random vector. We call e the error vector or noise vector. In this context,  $f(a^i)$  is sometimes called the signal.

Let  $b^1, \ldots, b^m \in A$ . Define  $z : \Omega \to \mathbf{R}^d$  by  $z_i = f(b^i)$  for  $i = 1, \ldots, n$ . So  $z_i$  is the random variable corresponding to the family at index  $b^i \in A$ . Then (y, z) is normal. We call the conditional density of z given y the predictive density for b given a.

**Proposition 1.** Define  $m_a \in \mathbf{R}^n$  by  $(m(a^1), \dots, m(a^n))^{\top}$  and define  $m_b$  by  $(m(b^1), \dots, m(b^m))^{\top}$ . Define  $\Sigma_a \in \mathbf{R}^{n \times n}$  by

$$\begin{pmatrix} k(a^1, a^1) & \cdots & k(a^1, a^n) \\ \vdots & \ddots & \vdots \\ k(a^n, a^1) & \cdots & k(a^n, a^n) \end{pmatrix}$$

and define  $\Sigma_{ba} \in \mathbf{R}^{m \times n}$  by

$$\begin{pmatrix} k(b^1, a^1) & \cdots & k(b^1, a^n) \\ \vdots & \ddots & \vdots \\ k(b^m, a^1) & \cdots & k(b^m, a^n) \end{pmatrix}.$$

 $<sup>^{1}</sup>$ Future editions will fix the re-use of the symbol m.

The predictive density  $g_{z|y}(\cdot,\gamma): \mathbf{R}^m \to \mathbf{R}$  of  $b \in A$  for design  $a^1,\ldots,a^n$  is normal with mean.

$$m_b + K_{ba}(K_a + \Sigma_e)^{-1}(\gamma - m_a)$$

and covariance

$$\Sigma_b - \Sigma_{ba}(\Sigma_a + \Sigma_e)^{-1}\Sigma_{ab}.$$
