

## **APPROXIMATORS**

## Why

We are given an element of some set, and want to find an element (in some subset) which is most similar to it.

## Definition

Consider a non-empty set, one of its subsets, and a similarity function on it. An *approximator* of an element of the set is any element of the subset. So we call the subset the set of *approximators*. One approximator may be more similar than another. An *optimal* approximator is a minimizer of the similarity function over the set of approximators.

## Notation

Let B be a non-empty set. Let  $A \subset B$ . Let  $d: B \times B \to \mathbf{R}$  be a similarity function. For  $b \in B$ , every  $a \in A$  is an approximator of b. An optimal b is a solution of

minimize 
$$d(b, a)$$

subject to 
$$a \in A$$
.
