

## **HYPERPLANES**

## Why

## Definition

A hyperplane in n-dimensional space is an (n-1)-dimensional affine set.

Since the n-1-dimensional subspaces are the orthogonal complements of the one-dimensional subspaces, they are the sets which can be specified by

$$\{x \in \mathbf{R}^n \mid x \perp b\}$$

for  $b \in \mathbb{R}^n$ . The hyperplanes are translates of these,

$$\{x \in \mathbb{R}^n \mid x \perp b\} + a = \{x + a \mid \langle x \rangle b = 0\}$$

$$= \{y \mid \langle y - a \rangle b = 0\} = \{y \mid \langle y \rangle b = \beta\},$$

where  $\beta = \langle a \rangle b$ .

## Characterization

**Prop. 1.**  $H \subset \mathbb{R}^n$  is a hyperplane if and only if there exists  $\beta \in \mathbb{R}$  and nonzero  $b \in \mathbb{R}^n$  so that

$$H = \{ x \in \mathbf{R}^n \mid \langle x \rangle b = \beta \}.$$

**Remark 1.** b and  $\beta$  are unique up to a common nonzero multiple. For example, b,  $\beta$  and 2b,  $2\beta$  give the same hyperplane.

**Remark 2.** The vector b is called a normal to the hyperplane.
